

The Impact of AIDS Treatment on Savings and Human Capital Investment in Malawi

February 13, 2015

Abstract

Antiretroviral therapy (ART), a treatment for AIDS, is rapidly increasing life expectancy throughout Africa. A longer life expectancy increases the value of human capital investment, though the effect on savings is theoretically ambiguous. This paper uses spatial and temporal variation in ART availability to evaluate the impact of ART provision on savings and investment. We find that ART availability significantly increases savings, expenditures on children, and children's schooling, particularly among HIV-negative individuals. These results are not driven by the direct health effects of treatment or reductions in caretaking responsibilities, but rather by improving perceptions of self-reported mortality risk.

This paper is a revised version of the first chapter of Baranov's dissertation at the University of Chicago. We thank Daniel Bennett, Pietro Biroli, Hoyt Bleakley, Erica Field, Alex Frankel, Sendhil Mullainathan, Matt Notowidigdo, Nathan Nunn, Emily Oster, and Rebecca Thornton for helpful suggestions. Essential feedback was provided by participants at NEUDC 2012, MWEIDC 2013, Young Lives Conference at Oxford and University of Chicago workshops. Baranov is grateful for support from the Beinecke Scholarship and the National Science Foundation GRFP. The data collection of the MLSFH has been approved by the IRB at the University of Pennsylvania and the National Health and Science Research Committee (NHSRC) in Malawi. The authors gratefully acknowledge the generous support for this research through National Institute of Child Health and Development (grant numbers R03HD058976, R21HD050652, R01HD044228, R01HD053781), the National Institute on Aging (grant number P30 AG12836), the Boettner Center for Pensions and Retirement Security at the University of Pennsylvania, and the National Institute of Child Health and Development Population Research Infrastructure Program (grant number R24 HD-044964), all at the University of Pennsylvania.

1 Introduction

The AIDS epidemic has dramatically decreased life expectancy in sub-Saharan Africa (SSA). In southern Africa, the region hardest-hit by the epidemic, life expectancy has fallen by nearly 25 percent in the past 15 years (UN Population Division 2012). The recent widespread availability of antiretroviral therapy (ART), a drug treatment that drastically slows the progression of AIDS, is reversing this trend. As a result, adult life expectancy has started to increase again in many SSA countries (Bor et al. 2013; Floyd et al. 2012).

This paper uses the expansion of AIDS treatment in Malawi to study the impact of sudden life expectancy gains on savings and investment in human capital.¹ A longer life expectancy encourages human capital investment by increasing the time horizon over which the investment pays out (Ben-Porath 1967; Becker and Tomes 1979). Additionally, changes in life expectancy are likely to affect savings decisions. Individuals may save more if they expect a longer retirement, but may, in fact, save less if they expect a longer and healthier working life (Bloom, Canning, and Graham 2003; Fogel 1994, 1997). If individuals accumulate savings as a form of insurance against the illness and death, we might expect savings to decline. Alternatively, if individuals accumulate savings for investment purposes due to credit constraints, savings might increase as long-term investments become more attractive. Since the relationship between life expectancy and savings is theoretically ambiguous, it is ultimately an empirical question and one that few studies have explored causally.²

Using longitudinal survey data, we estimate the impact of ART availability on savings, expenditures on children’s human capital, and children’s schooling. Our identification relies on spatial variation in ART availability as measured by the respondents’ distance to the ART facility. By combining precise GPS locations of households with administrative records on locations and start-of-ART-service dates for clinics, we calculate the respondents’ exact distance by road to their nearest ART facility. We employ a difference-in-difference strategy with individual fixed effects, comparing outcomes before and after ART became available

¹ART increases life expectancy by reducing the mortality risk from engaging in risky sexual behavior: it reduces both the likelihood of death conditional on infection and the transmission probability. However, the effect of ART on life expectancy is mediated through the behavioral response, since individuals may increase risky sexual behavior (Lakdawalla, Sood, and Goldman 2006; Wilson, Xiong, and Mattson 2011; De Walque, Kazianga, and Over 2010; Oster 2012; Friedman 2012). In South Africa, recent evaluation of demographic surveillance data has shown that objective life expectancy has increased as a result of ART and HIV incidence has declined, suggesting that even if individuals respond by increasing risky sexual behavior, the response does not overwhelm the benefits of ART (Bor et al. 2013; Tanser et al. 2013).

²Many studies have looked at the effect of longevity on savings in cross-country analyses, generally finding a positive correlation (Lee, Mason, and Miller 2000; Bloom, Canning, and Graham 2003; Zhang and Zhang 2005). Some studies have looked at the effect of HIV on savings in cross-country regressions, but no consensus has yet emerged (Bonnell 2000, Lammers, Meijdam, and Verbon 2007). To our knowledge, only one other study attempts to identify the causal relationship between life expectancy and savings. Thornton (2012) finds that learning one’s HIV status had only short term effects on subjective beliefs about one’s HIV status, and no apparent effects on savings, expenditures, employment, and long-term subjective beliefs. Individuals who learn they are HIV-negative continue to worry about becoming infected in the future. Godlonton and Thornton (2013) suggest this might be an important factor, finding that village-level testing is more important for HIV beliefs and behavior.

at the facility along the distance gradient.³

Malawi was severely affected by the AIDS epidemic, with a national prevalence that peaked at 15 percent in 1997. In 2003, through support of large international donors and governments, the Malawian government started to make ART available for free, and the ART program has been expanding rapidly since. The scale-up of the program, widely regarded as a public health success, has resulted in measured declines in adult mortality (Jahn et al. 2008; Floyd et al. 2012).⁴ And while HIV-positive persons gain the most from treatment becoming available, HIV-negative individuals also face large gains in life expectancy through reductions in future risk.

We are able estimate the effect of ART availability among the HIV-negative respondents and over a short time horizon, thereby minimizing concerns of estimating the direct health effects of treatment, population shifts, and other general equilibrium effects. Additionally, the data contain information on self-reported mortality risk, allowing for a unique analysis linking changes in outcomes to changes in subjective expectations. Since subjective expectations are the determining factor in decision-making, measuring subjective probabilities provides a direct test of the theory (Manski 2004).

The ART rollout in Malawi provides a good setting to study the effect of life expectancy on investment and related life-cycle behaviors for a number of reasons. UN-based estimates of life expectancy gains from eliminating AIDS mortality in Malawi are 12.7 years. Thus, the life expectancy gains are large and occur primarily as a result of changing *adult* mortality risk.⁵ HIV/AIDS affects individuals after major human capital investments have been made but before they have retired from the labor market. Moreover, the positive shock from eliminating mortality risk from AIDS provides a cleaner experiment than the negative shock from the arrival of HIV, because the negative shock is necessarily accompanied by death, which has large and immediate direct consequences for survivors. Finally, the shock to life expectancy is both long-term and impacts the general population. Thus, it is more informative about the effect of life expectancy on human and physical capital accumulation in the macroeconomy as a whole, which is the mechanism typically studied in growth theory (Solow 1956; Koopmans 1965; Romer 1986).⁶

³Other studies, such as Friedman (2012); McLaren (2010), have similarly used distance to ART facilities for identification. A notable feature of our analysis is the spacial precision of the data, which allow us to find comparison households within a 15 kilometer radius.

⁴This effect of ART on mortality has not remained unnoticed by the local populations. For example, coffin sales declined, funerals became less common, and improvements in the health and economic activities of HIV-positive persons receiving ART have been widely recognized (Mwagomba et al. 2010; Ashforth and Watkins 2013; Thirumurthy et al. 2012a).

⁵We emphasize that the life expectancy gains result from changing adult mortality risk, as distinct from infant or old-age mortality. The latter should not impact investment decisions through the mechanism we are trying to identify (Cervellati and Sunde 2013). Many previous studies using cross-country regressions consider how life expectancy impacts education and growth (Acemoglu and Johnson 2007; Lorentzen, McMillan, and Wacziarg 2008; Bloom, Canning, and Fink 2009; Hansen 2013); however, they rely on life expectancy gains resulting primarily from reductions in infant mortality.

⁶Oster, Shoulson, and Dorsey (2012) estimate the causal impact of limited life expectancy on human

We find a strong response in savings behavior: halving the distance between a respondent and the ART facility—a reduction of approximately 5 kilometers for the average respondent—results in an increase in the propensity to report any savings by 10 percentage points. Additionally, we find that ART availability increases investment in human capital. Reducing the distance by half increases expenditures on children’s education by US\$3.08 and children’s medical spending by US\$0.68 per child (combined, an increase of 3% of annual reported earnings spent on each child). We also observe substantial gains in educational attainment for children of the respondents near ART. Halving the distance to ART implies an increase in schooling by 0.3 years.

The identifying assumption for our analysis is that individuals living near and far from ART facilities would have similar trends in absence of ART. Using pre-period data, we show that trends in outcomes and other characteristics are not correlated with proximity to the ART facility. The results are robust to including controls for spatial and demographic characteristics, reported economic shocks, and participation in other government aid programs. While we find that ART availability increases savings and investment behavior, we do not observe changes in reported earnings, suggesting that the results are not driven by income shocks. The magnitudes are also similar and remain significant among HIV-negative respondents, indicating that the results are not driven by the direct effect of respondents receiving life-saving medication. And while it is a-priori plausible that mechanisms such as a reduced morbidity of HIV-positive persons receiving ART lead to reduced care-taking responsibilities for HIV-negative persons, our results indicate that mechanisms such as household caretaking burdens from AIDS related illness, death, and orphanhood, do not explain our findings of the effect of ART availability on investment.⁷

We find that ART availability measurably decreases self-reported mortality risk. We calculate the implied change in *subjective* life expectancy based on the impact of ART proximity on perceived mortality risk. The estimates suggest that respondents’ perceptions about mortality reduction are roughly in line with UN-based estimates: reducing distance to an ART facility by 5 kilometers increases subjective life expectancy by 6.8 years. Taken together, these findings suggest that individuals actively adjust their investment decisions in response to a subjective lengthening of their investment horizon.

capital investment using genetic variation in the population of Huntington disease patients. The study provides a well-identified estimate of the elasticity of demand for education with respect to years of life expectancy in the context of Huntington disease (HD) patients. Due to the emphasis on the difference between HD patients’ life expectancy and that of the population, the results may not extend easily to developing countries.

⁷Our approach is unable to rule out other general equilibrium effects of ART that may impact investment. [Thirumurthy, Zivin, and Goldstein \(2008\)](#) find that the benefits of ART to health and labor market participation occur with a delay, so the effects on investments of changes in wages and demand are likely to be lagged in this setting. The very short time frame during which we observe the response to ART mitigates concern that our estimates of the effect of ART availability on investment are capturing these other spillovers and general equilibrium effects. Consistent with this, we find no effects of ART on labor earnings and other expenditures (Section 5).

Last, we calculate the marginal effect of life expectancy on schooling. The increases in educational attainment reported above reflect changes in life expectancy for both parents and children. Therefore, to isolate the effect of an additional year of a child’s life expectancy, we exploit the differential change in life expectancy by gender. Higher HIV prevalence rates and younger ages of infection imply that women gain 3.3 more years in life expectancy from eliminating AIDS mortality than men (UN-based estimates). In a triple-difference approach, our estimates of the additional gain in schooling by gender imply that one additional year of life expectancy increases schooling by 0.1 years.

This study contributes to the literature by investigating the consequences of expanded ART availability on life cycle dynamics in the general population. The benefits of ART availability are not necessarily restricted to HIV-positive individuals. For example, HIV-negative persons face future risks of HIV infection, the consequences of which are reduced by ART. Previous studies on ART have focused on the direct effect of treatment on HIV-positive persons (Thirumurthy et al. 2012b,a), or the effect of ART on risky sexual behavior (Lakdawalla, Sood, and Goldman 2006). However, very few studies exist that have evaluated the potential benefits of ART expansion as incurred by the general population.

Our human capital results add to a growing literature on the impacts of life expectancy on human capital (Jayachandran and Lleras-Muney 2009; Fortson 2011; Oster 2012). Our findings are consistent with that literature. Furthermore, the observed changes in subjective life expectancy allow us to be more confident in the mechanisms driving the results.⁸

Our savings results provide another channel through which life expectancy may impact growth. Standard models of economic growth include savings as a driver of growth, although the impact of life expectancy on this behavior is theoretically ambiguous. Our evidence suggests that, higher life expectancy does prompt more savings. The impact of life expectancy on growth is therefore greater, even, than would be suggested by the human capital channel alone.

2 Context

Malawi is one of the countries hit hardest by the AIDS epidemic, with nearly one million people currently living with HIV/AIDS, and it is one of the world’s poorest countries with a GDP per capita of \$340 (PPP adjusted \$918). Adult HIV prevalence peaked at 14.7 percent

⁸Economists rarely measure subjective expectations and must rely on actual population shifts in adult mortality to identify the effect. For example, Jayachandran and Lleras-Muney (2009) find that the reduction in maternal mortality in Sri Lanka during the mid-20th century substantially improved female education outcomes. Fortson (2011) exploits geographic and time variation in HIV prevalence in Sub-Saharan Africa to estimate the effect of the HIV/AIDS epidemic on human capital investment. While these studies provide evidence in support of the standard model of human capital accumulation, neither provide direct evidence of the mechanism. Moreover, empirical strategies in macro-based studies over long time horizons must rely on changes in life expectancy that affect population dynamics and are likely to influence decisions in ways that are not related to changes in expectations (Santaaulalia-Llopis 2008; Ardington et al. 2012). For example, one important consequence of changes in mortality is the immediate effect on family structure. After a death of an adult, the dependency ratio in that household increases.

in 1998 and has steadily declined since (UNAIDS 2010). The current HIV prevalence, at 11 percent, is still one of the highest in Africa (2010 Malawi DHS). Malawi's population, 15.4 million, is over 80 percent rural and supports itself primarily through subsistence agriculture.

The educational attainment in Malawi is low. The mean years of schooling is 4.2 for adults over 25; and net secondary school enrollment, at 24%, is very low (WDI 2010). Qualitative interviews suggests that risk perceptions about HIV/AIDS factor into parental decisions about their children's education (Grant 2008). Primary education goes up to grade eight and is not compulsory. The official starting age is six years old; but, it is not uncommon for children to start considerably later. While the government established free primary education in 1994, which increased attendance rate by approximately 50% (Kadzamira and Rose 2003), families are still responsible for uniforms and school supplies and must consider the opportunity cost of enrollment as children often participate in wage labor or help with household chores.⁹

Life expectancy at birth in Malawi is 54 years, and AIDS is the main cause of adult mortality (AVERT 2012). In direct response to the previous governments' refusal to acknowledge the epidemic, in 2003 the Malawian government announced it would provide free antiretroviral therapy to HIV patients. The ART program was paid for largely by the Global Fund, which contributed a total of US\$294 million. The HIV Unit in the Ministry of Health (MOH) has been responsible for the dissemination of the medication, the training of nurses and doctors, and other logistics associated with the rollout. The MOH maintains detailed records of the rollout, and performs site checks at all ART facilities on a quarterly basis. Other notable features of the rollout include its systematic and well-monitored expansion, the use of existing clinics and hospitals as the primary mode of expansion, and a short time frame between when clinics were selected to provide ART and when they actually began providing the medication.

The Ministry of Health (MOH) began providing free ART in June 2004 at nine clinics. By the end of 2010, the number of clinics providing ART had grown to nearly 300 with over 350,000 patients ever initiated on ART, and 211,000 receiving treatment in 2010.¹⁰ The rollout occurred in two stages: Round 1 (2004-05) had the most rigorous requirements for clinics, and 60 sites (mostly hospitals and large clinics) were chosen to begin providing ART. In 2006, the government outlined a 5-year plan to expand its ART program with the goal of attaining 100% coverage of those in need by 2010. To that end, the MOH aimed

⁹In 2006, an estimated 29-37% of children aged 5-17 in Malawi were working, more than half on them in agriculture (National Statistics Office Malawi 2008). Children work in the agricultural sector, often alongside their parents on commercial farms and frequently perform domestic work to allow adults to work longer hours in the fields (US Department of Labor 2002).

¹⁰By June 30, 2010, there were 396 clinics (290 static and 106 outreach) in the public and private sector that had registered a total of 359,771 patients on ART. Although private clinics also receive the ART medication at no cost from the MOH, they are permitted to charge patients a small fee. The private sector accounts for a very small part of the ART rollout, and less than 4% of patients were ever initiated on ART through the private sector (MOH 2011 Quarterly Report).

to maximize geographical coverage and relaxed the standards for facilities, considering all clinics with at least one clinician and one data clerk. Although clinics that provide ART are generally bigger and better equipped than those that do not, the differences are substantially smaller for sites that began providing in later stages of the rollout (Appendix Table D.2). The expansion of ART has continued after 2010, which is the last year covered by our data, and in December 2013 there were 689 clinics providing integrated ART services to 472,000 HIV+ persons (more than 100,000 of whom were enrolled during 2013 alone) who have a reported 12-month survival rate of 78%, slightly below the WHO recommendation of 85% (Government of Malawi 2014).

Enrolling and adhering to ART requires significant *ongoing* effort and resources from patients. ART patients are required to visit the clinic every two weeks to receive medication in the first month after initiation, then every month for the next six months, and every three months thereafter. Limited transportation infrastructure, a poor road network, high fuel prices, and nonexistent public transportation make it difficult for individuals with HIV, particularly those who are sick enough to be eligible,¹¹ to travel long distances to receive treatment.¹²

Adherence to ART in Malawi and other SSA countries is only about 80% after 12 months of treatment initiation, not as high as one would apriori expect given that ART is lifesaving for HIV+ persons (Rasschaert et al. 2012). Anecdotal evidence from clinic visits also suggests that a large share of ART patients lost to follow-up are those living far from clinics (Baranov 2012), and a number of recent studies in Malawi tracking and interviewing HIV+ patients who were lost to follow-up suggest that transport costs are a major factor in obtaining treatment, and were explicitly mentioned by 30% of the respondents as the primary reason for failing to obtain treatment.¹³ One qualitative study from Uganda reported that even patients who have not yet been initiated on ART expressed anxiety about getting enough money to cover transport to the clinic (Tuller et al. 2010). Distance to the health facility is used by health planners to define access to health services, and a number of recent studies from Sub-Saharan Africa have found that geographic distance to a health facility is an important factor in child mortality and other health outcomes.¹⁴

¹¹The guidelines for treatment eligibility were determined by the Ministry of Health based on WHO recommendations. As there are only a few CD4 machines in Malawi, eligibility is determined solely by clinical symptoms of Stage 3 (advanced) or 4 (severe) AIDS. The WHO later revised the recommendation to include individuals with higher CD4 counts. The MOH released new guidelines in 2011 that reflected the WHO revisions; however, this change is not pertinent to our analysis.

¹²Transportation infrastructure is generally poor. Only primary roads are paved; secondary and tertiary roads are normally dirt roads and become muddy and difficult to navigate during the rainy season. Few people own cars or motorcycles. The most common modes of transportation are walking, biking, hiring a bike taxi, and hitchhiking (though it is customary to pay the driver).

¹³See, for example, Tabatabai et al. (2014); Rachlis et al. (2013); McGuire et al. (2010); Say and Raine (2007); Zachariah et al. (2006). Another recent study in Malawi's Karonga District has attributed improved treatment adherence in this district to the decentralization of ART provision that importantly reduced distances to the nearest ART clinic (Koole et al. 2014).

¹⁴See, for example, McLaren, Ardington, and Leibbrandt (2014); Lucas and Wilson (2013); Okwaraji

3 Estimation

3.1 Data

This paper uses data from the Malawi Longitudinal Study of Families and Health (MLSFH), which is an ongoing panel survey that has been conducted since 1998 (Kohler et al. 2014). The MLSFH cohorts were selected to represent the rural population of Malawi, where the vast majority of Malawians live in conditions that are similar to those in the rural areas of other countries with high HIV prevalence. The MLSFH collected GPS coordinates for sampled households and performed HIV testing in 2004, 2006, and 2008. The survey is conducted in three distinctive districts of Malawi: Rumphu in the north, Mchinji in the center, and Balaka in the south. The sample is entirely rural and not necessarily meant to be nationally representative, although key characteristics are similar to those found in the Demographic and Health Survey (DHS). Attrition in the MLSFH is high: approximately 25 percent of the 2006 sample is lost to follow-up by 2010. However, this attrition is not correlated with ART proximity, and our attrition analysis, described in detail in Section A.2 in the Data Appendix, suggests that attrition is not a threat to our identification strategy.¹⁵

ART became available at clinics within the MLSFH study regions shortly before the 2008 survey.¹⁶ The main analysis uses survey rounds from 2006, 2008, and 2010. Our results are estimated using the set of respondents that are present for all three years of the survey from 2006-2010.¹⁷ The data from the 2004 wave allow us to test for differential pre-ART changes. However, some outcome variables, notably savings and subjective expectations, were not available in the 2004 round.

We use distance to the nearest ART facility, a measure of access, as the source of identifying variation. Using precise GPS data on the locations of respondents and clinics, we calculate the distance to the nearest facility providing ART at the time of the survey. To ensure that the most relevant information is captured, we combine rich data on road networks to calculate the distance *by road* to a nearest facility.¹⁸ We also calculate the distance to the nearest clinic (regardless of ART status),¹⁹ market, school, and major road. These vari-

et al. (2012); Okwaraji and Edmond (2012); Guenther et al. (2012); Schoeps et al. (2011).

¹⁵Attrition is comparable to that of other longitudinal datasets in developing countries (Alderman et al. 2001). See Kohler et al. (2014) and Anglewicz et al. (2009) for a detailed summary of the data and attrition in the MLSFH.

¹⁶ART was available at the clinics for an average of 7 months prior to the 2008 interviews. Using a time-varying measure of exposure to ART (e.g. months ART was available interacted with distance to the facility) yields similar results (not shown).

¹⁷This was done in order to maximize the number of observations but still maintain a balanced panel. The results are similar using the entire sample of respondents (available from the authors by request).

¹⁸Distance calculations were computed using ArcGIS Network Analyst. Data on road networks were provided by the National Statistics Office of Malawi. As can be seen from Figure 1, the road network is very dense and captures smaller dirt roads in addition to larger and paved roads. The correlation between straight-line and by-road distance was 0.9 and the results are robust to using straight-line distance (not shown). Distance by-road yields more precise estimates, reflecting less measurement error.

¹⁹All clinics in our sample provided HIV Testing and Counseling even in 2006.

ables serve as important controls, as distance to one location is correlated with other spatial features that may pose a threat to identification. Additionally, we control for population density. Figure 1 shows a map of these features and the survey area of sampled households in the Mchinji district.

Before 2007, the nearest ART facility for most respondents was more than 25 kilometers away (the median distance was 27 kilometers), rendering ART virtually inaccessible for the population in the rural MLSFH study region. By 2008, ART arrived to at least one clinic within the survey area of each region, and the median distance to the nearest ART facility became 8.9 kilometers. All respondents are at least a kilometer away from ART, which makes it unlikely that we are picking up effects from higher foot traffic near the clinics. Several clinics also began providing ART after the 2008 survey in the sample regions. These clinics were generally farther away from the respondents than existing ART facilities. In the analysis, we use the 2008 distance to ART facility interacted with year as the identifying variation. Figure 2 shows the distribution of distances to respondents’ nearest ART facility in 2008.²⁰ The distribution of distances is not uniform and differs by region (see densities by region in Figure 2, right panel), and at any given distance to ART, the regions are not equally represented. To ensure we capture the relevant variation over time, we include region-by-year controls throughout the analysis.

Table 1 provides summary statistics of the data being used from survey year 2006, before treatment became available (“pre-ART”). Panel A describes the demographic and economic characteristics of the sample, and Panel B describes HIV and risk perceptions.²¹ In addition to the standard battery of questions in a household survey, beginning 2006 the MLSFH includes a module on subjective expectations, which elicits respondents’ beliefs about probabilities using an interactive elicitation technique (the “*bean method*”). Individuals are asked to allocate the number of beans (0 to 10) between two plates to reflect the probability of an event occurring versus not occurring. Among other things, respondents were asked to assess their own mortality risk over a 5-year horizon. Delavande and Kohler (2009) document that respondents from Malawi provide meaningful expectations, including with respect to their own mortality, in probabilistic format according to various criteria: most respondents provide probabilities that are consistent with basic properties of probability theory, the subjective expectations are systematically correlated with observable characteristics (such as gender, age, education, and region of residence) in the same way that actual outcomes vary with these variables, and expectations about future events vary across individuals in the same way as individuals’ past experience does.²²

²⁰The distance to the nearest ART facility changed for only 30 respondents in 2010. Figure D.2 plots the distribution of distances to the nearest facility by year, showing little difference between 2008 and 2010. The results are unchanged if we use time-varying ART proximity instead of the 2008 distances.

²¹We report all monetary values in USD using the 2010 exchange rate of 150 MWK = 1 USD.

²²For a broader discussion of the importance of collecting data on subjective expectations in low and middle income contexts, and their usefulness in economic analyses, see Delavande (2014).

Panel B in Table 1 reports summary statistics for the respondents’ own 5-year mortality risk, perceived own-HIV risk, perceived HIV prevalence, and whether respondents report being worried about AIDS.²³ These measures allow us to explicitly link changes in economic behavior to measured changes in subjective expectations. We use the 5-year subjective mortality risk to calculate the implied effect of ART on subjective life expectancy.

Table 1 Panel C summarizes pre-ART savings and expenditure outcomes of interest for our analysis. Respondents were asked to report the total amount of money they have in savings (such as a bank account, savings group, or cash).²⁴ Additionally, respondents reported expenditures on their children’s education, medical services, and clothing in the past three months. Panel D of Table 1 shows summary statistics for the sample of children of the respondents who are linked over time using data from the household rosters.²⁵ The main outcome for children used in our analysis is grade completion, and we additionally report statistics on the child’s subjective health (as reported by the parent; 1= poor health, 5 = excellent health). Panel E reports statistics of spatial characteristics.

Distance as Access

Respondents knew about the existence of ART well before it became available in their area. Anecdotal evidence suggests that news spread quickly about the existence of ART, referred to as “mtalikitsa moyo” or “prolonging life” in Chichewa. The country-wide ART rollout was featured prominently in national newspapers, radio, and TV. By 2006, 95 percent of respondents had heard of ART, which was at the time available in urban and peri-urban areas of Malawi. Many MLSFH respondents already had relatively accurate perceptions of the effect of ART on mortality of HIV+ persons: for example, when asked in 2006 about survival probabilities of hypothetical HIV+ individuals, they reported substantially higher 5- and 10-year survival rates for HIV+ persons on ART treatment as compared to HIV+ persons not on treatment (Delavande and Kohler 2011). Combined, these patterns suggests that our findings are driven by individuals responding to access, as opposed to learning about the new technology.

Even though word spread of the existence of the drugs, individuals may not have known where the drugs were available locally. However, even if locations of nearest ART facilities were known, distance serves as a proxy for access to ART as it determines the time and monetary cost of getting treatment. For example, in 2004, as part of an experiment used in Thornton (2008), participants of the MLSFH were offered monetary incentives to obtain their HIV test results at temporary Voluntary Counseling and Testing centers (VCTs). The study finds that distance is an important factor in determining whether individuals obtained

²³We provide two measures of the respondents’ perceived HIV risk. One is the perceived risk using the bean method, and the second is the likelihood of HIV infection using the Likert scale (0=no likelihood, 1=low, 2=medium, 3=high likelihood).

²⁴Fewer than 5% of respondents belong to savings groups.

²⁵See the Data Appendix A for additional details of this linkage process.

their results; individuals who lived within one kilometer of the VCT were more than twice as likely to get their results as those who lived between 3 and 4 kilometers away.²⁶

While we do not have data on ART uptake over time, we collected data on ART uptake among the subsample of MLSFH participants interviewed in 2012.²⁷ Of the HIV-positive respondents, 70% are on ART, and being 5 kilometers closer to the ART facility is associated with a 21 percentage point increase in the likelihood that the respondent is on ART ($p = 0.07$, $n = 23$). Although the sample size is small, these results echo the findings from studies tracing patients who were lost to follow-up.²⁸

Additionally, distance facilitates the spread of information about ART availability at a particular clinic.²⁹ Knowledge of local availability may be more sensitive to distance for individuals who are HIV-negative as they are less likely to actively seek information about treatment options. While the country-wide existence of ART was known broadly, local information about treatment options relied primarily on word-of-mouth. However, because HIV/AIDS is heavily stigmatized, individuals are reluctant to talk about specific information, like innovations in local ART availability, for fear of signaling HIV status to the community. Thus distance plays an important role of information transmission and common knowledge about local treatment options.

In our analysis, we highlight the results for HIV-negative respondents, who are anticipating the need for treatment in case they become infected in the future (or for those that do not know their status, the probability that they are already infected). It is possible that respondents anticipate that ART will be available near them by the time they will come to need it, and this should bias our estimates toward finding no effect.³⁰

3.2 Empirical Strategy

We estimate the effect of ART availability on savings, child expenditures, and schooling outcomes. Using a difference-in-difference strategy, we compare outcomes of respondents living near an ART facility to those living far, before and after ART became available.

²⁶The location of the VCTs was randomized based on the straight-line distance from respondents' households. VCTs were not placed further than 4km away, as they were deemed too far. Voucher amounts, randomized by letting each respondent draw a token out of a bag indicating the monetary amount, were redeemable two to four months after sample collection.

²⁷This sample included individuals over 45 years old, approximately 1,200 respondents (Kohler et al. 2014).

²⁸One study from another region of rural Malawi finds that, of the traced individuals who survived (and thus able to be interviewed), 30% of patients defaulted because of transport and time costs of accessing treatment. In this study, the patients all lived within a 15 kilometer radius of a treatment facility (McGuire et al. 2010).

²⁹Oster and Millet (2011) demonstrate that distance to a call center in India is an important factor in the spread of information about requirements to obtain employment. Notably, they find that the spread of information is highly localized and that the information did not spread to individuals living more than 5-6 kilometers away from the centers.

³⁰Because of the rapid scale-up and limited resources, the ART rollout provided treatment out of existing facilities and did not ever build new facilities. It is unlikely that individuals far from any clinics would anticipate access in the 5-10 year horizon, without any observed construction. Indeed, the rollout to date has not made ART available for people living far from clinics.

Distance to the nearest facility proxies for ART availability, incorporating both travel cost and information. The main regression analysis is based on the following specification:

$$y_{it} = \beta Post_t \times Proximity_i + \alpha_i + \delta_{rt} + \varepsilon_{ijt} \quad (3.1)$$

where y_{it} is the outcome for respondent i in village j , and region r , and time period t . $Post_t$ is an indicator for years 2008 and 2010 of the survey, i.e., the years after which ART became available in the MLSFH study regions.³¹ $Proximity_i$ is the proximity to the nearest ART facility in 2008 and is time-invariant. The baseline specification also includes individual-level fixed effects, α_i , which absorb the time invariant proximity variable, and region-by-year fixed effects, δ_{rt} , which absorb the indicator for the post period. Standard errors are clustered by village and are robust to heteroskedasticity.

We parametrize ART proximity as the negative of log-distance, though the results are robust to other specifications of functional forms such as inverse, linear, dummies for the three distance groups, and so on.³² However, this parametrization allows for a convenient interpretation of the coefficient as the effect on the outcome for an individual if the distance to an ART facility were reduced by half.³³ This corresponds to a decrease in distance of 5.68 kilometers from the mean (and median) distance of 9 kilometers. We also show the results nonparametrically (see Appendix Figure D.5).

Identification Tests

Our primary identification assumption is that distance to ART is not correlated with unobserved characteristics of respondents that affect trends in outcomes. One way our results arise spuriously is if people near ART are systematically different from those who are far and would exhibit different trends in outcomes regardless of ART becoming available. For example, respondents near health facilities may become more optimistic over time because they have easier access to healthcare, or respondents near the major roads or trading centers may earn more because they have better economic opportunities. While we cannot test the unobservables directly, our dataset contains a rich set of observed characteristics. Thus, we are able to test if these characteristics are balanced along the distance gradient in the pre-ART period.

Table 1, column 3 reports the coefficient on ART proximity, parameterized as the negative log of distance, when regressing each characteristic on ART proximity (controlling

³¹In all specifications, we allow for separate indicators for 2008 and 2010.

³²Ex ante, we would not expect the effect of distance to be linear, since a reduction in distance by 2 km would likely have a much bigger impact at a distance of 5km than at 10km (both because of fixed costs of transport and because of patterns in information spread). The nonparametric results in Appendix Figures D.4 and D.5 suggest that the effect of distance is, indeed, nonlinear.

³³This interpretation of the semi-elasticity is only accurate for small changes in distance. The precise interpretation of the coefficient is the impact of reducing distance by a factor of e , that is when $\ln(\frac{d_1}{d_2}) = 1$, which means that distance must be reduced by more than half. This corresponds to a decrease in distance from the mean (9 km) by 5.68 km.

for region dummies). The coefficients, which pertain to the pre-ART period (2006), can be interpreted as the expected change (non-causal) in that characteristic as we move 5.68 kilometers closer to the ART. In column 3, Panel E, we note that ART proximity is correlated strongly with other spatial characteristics. For example, moving 5.68 km closer to ART means that individuals are 3.72 km closer to a major market. There are some other patterns. In particular, respondents near ART do *not* exhibit more savings and investment behavior, our outcomes of interest, in the pre-ART period. They are more likely to have a metal roof, and labor income is higher near ART (significant at 10 percent), though other wealth characteristics are not significantly correlated. Additionally, in this pre-ART period, respondents near ART appear to have higher perceived HIV risk and mortality risk, and lower mental health scores. On the other hand, in the pre-ART period, actual infection risk and physical health scores do not vary significantly with ART proximity, as one would expect, and individuals are not significantly more likely to know someone on ART.³⁴ Parents report that their children are less likely to be in excellent health near ART. Overall, the pre-ART associations in Table 1 indicate that individuals near ART do not appear to be systematically different based on background characteristics before ART became available.

Column 4 of Table 1 shows the coefficients on ART proximity after controlling for spatial characteristics and population density. The sample achieves better balance along the distance gradient with the spatial controls, suggesting that many of the differences found column 3 were attributable to the correlation in spatial characteristics and not inherent to the distance to the ART facility, per se. Without spatial controls, a joint test of all variables in Panels A-C gives an F-statistic with a $p > 0.11$. Controlling for the spatial characteristics, a joint test yields an F-statistic with a $p > 0.73$.³⁵ We note, however, that a few pre-ART characteristics remain unbalanced: respondents near ART still reported a higher perceived HIV risk (using the bean method, though not using the Likert scale).³⁶ Households near ART are still more likely to have a metal roof (though the coefficient is significant only at 10 percent) and are more likely to have a mobile phone.

All of our subsequent results are robust to including controls for spatial characteristics, where the effect of ART is estimated using a comparison group that is equidistance to (non-ART) medical facilities, schools, major roads and markets. Specifically, we control for proximity (interacted with $Post_t$) to a primary road, any clinic (regardless of the availability of ART services at the clinic), major trading center, school, and population density.

³⁴This is plausible as rural Malawians tend to have fairly large social networks, including generally also family members and friends in peri-urban areas (Myroniuk, Prell, and Kohler 2013). And in the pre-ART area in the MLSFH study regions, persons on ART known to MLSFH respondents would most likely be individuals residing in such peri-urban areas that received ART prior to the MLSFH study regions.

³⁵While the spatial characteristics are all highly correlated, they are not collinear. Regressing ART proximity on the other spatial controls yields an $R^2 = 0.56$, leaving a substantial amount of variation for identification.

³⁶We may also worry that the results in subjective expectations are driven by mean reversion. Controlling for pre-period mortality risk interacted with year does not change our results (not shown). In Table 7, Column 6, we also show the results are robust to controlling for pre-period HIV risk trends.

Proximity is parameterized as the negative log of distance. Moreover, the point estimate on $Post_t \times Clinic\ Proximity_i$, where $Clinic\ Proximity_i$ is the distance to any clinic (regardless of ART), shows the effect of being near any medical facility and provides a useful placebo test.

Additionally, our results are not spuriously driven by initial demographic differences: we include pre-period levels of characteristics interacted with $Post_t$ to account for compositional differences by ART proximity, and allow for differential trends among these demographic groups. We include standard demographic controls: pre-period wealth, age, gender, education, household size, and marital status. In addition, we include dummies for roof structure and if the respondent had a mobile phone in the pre-ART period, since these were correlated with ART proximity even after controlling for spatial characteristics.

The identification assumption behind our difference-in-difference estimation is that the sample is balanced in trends, not levels, along the distance gradient. Table 2 tests for differential pre-ART changes for variables that are available in 2004: Panel A reports pre-trends for the demographic and economic characteristics, Panel B reports trends for HIV and risk perceptions, and Panel C shows pre-trends in child expenditures, the outcome of interest. The table shows no evidence of differential pre-trends in outcomes by distance to ART, with or without additional spatial controls (columns 3 and 4). The lack of significantly correlated changes in other economic variables, HIV status, or risk perceptions suggests that the identification assumption is valid.³⁷ Since the subjective expectations module was added only starting 2006, we are unable to test pre-trends for the subjective mortality risk measure. A weaker test, using cross-sectional data from 2006, is to compare trends in subjective mortality risk using cohort-of-birth across distance groups. For example, a regression of subjective mortality risk on year-of-birth interacted with ART proximity, controlling for year-of-birth and ART proximity, yields a small and statistically insignificant coefficient. Visually, Appendix Figure D.3 show the trends in 5-year subjective mortality risk in 2006, for three distance groups. It's clear that older respondents have higher mortality risk, and respondents near ART report a higher mortality risk, though the trends run parallel.

³⁷Individuals near ART were more likely to acquire a mobile phone prior to ART coming online, and in 2006, families near ART were more likely to have a mobile phone. This is a potential threat to identification, since mobile phone uptake may be a proxy for forward-looking behavior (or individuals who had mobile phones early were more likely to take up new technology). Alternatively, families with mobile phones may have an advantage in farming or selling goods at the market. We control for if the respondent had a mobile phone in the pre-period in the regressions to ensure the results are not driven by this group. The results are similar if we control for the *change* in mobile phone between 2004 and 2006 interacted with year (not shown). However, this is not surprising since almost no one had mobile phones in 2004 (0.5%), so the change between 2004 and 2006 behaves identically to the levels in 2006. However, in 2006, very few respondents had mobile phones—only 3.5 percent. By 2008, that number grew to 24 percent and by 2010 to 41 percent. Even by 2008, mobile phone ownership was no longer correlated to ART proximity. Controlling for time-varying mobile phone take-up does not affect our results (not shown). This suggests that although early take-up of mobile phones (by a very small number of respondents) is correlated with ART proximity, it is unlikely to be generating our results spuriously.

Other Threats to Identification

A potential threat to identification is that proximity to ART may be correlated with the provision of other government aid programs such as subsidized maize, agricultural inputs subsidies, or other health initiatives. The MSLFH asks respondents about whether the household was a recipient of a number of social support programs including food and education subsidies, nutrition programs, agricultural supports, and unconditional cash transfers. Overall, 75% reported receiving any government aid, and participation in is not correlated with ART proximity in 2006 (and, if anything, negatively correlated with ART proximity in 2010). Consistent with this, we show the results are robust to including controls for household participation in such programs.³⁸

Another concern is that areas near ART facilities may have different unobserved shocks due to their spatial proximity to landmarks that may also impact individual outcomes. For this reason, we also include controls for reported economic shocks by household, though these are not correlated with ART availability. Economic shock variables include income loss, property loss (e.g. fire or flood), death of a breadwinner, divorce, poor harvest, large grain price fluctuations, and other shocks.³⁹

Finally, we may also worry that respondents who are more likely to benefit from ART move closer to the facilities. Rental housing is largely not available in these villages, so individuals would need to move their farm and build a house in order to relocate. Consistent with this, we find that attrition is not correlated with ART proximity (see Appendix Table D.1 and the discussion in the Appendix Section A.2). We exclude attriters, individuals who completed the survey in 2006 but not in 2008 or 2010, from the entire analysis to ensure that the results are not biased by the changing demographic composition of the sample over time, though the results are similar using the full sample (not shown).

4 Results

To illustrate the identifying source of variation, Figures 3 and 4 plot the main outcomes variables over time by splitting the sample into three groups: near (within 6 kilometers of ART), middle (between 6 and 12 kilometers), and far (more than 12 kilometers).⁴⁰ Figure 3 shows the fraction of respondents with any savings and average total savings. Data for

³⁸These data were only collected in 2006 and 2010. The questions asked if the respondent participated in these social support programs (eleven in total) in the previous two years. For inclusion as controls, we created 11 variables for participation, which only vary between the pre- and post-ART periods, and interacted these with $Post_t$.

³⁹These variables on economic shocks are first available in 2008. Hence, there is not enough data to include these shocks as time-varying controls. Instead, we calculate whether the respondent has ever experienced a particular type of shock and include this set of variables (7 in total) interacted with $Post_t$ as controls. This approach measures the respondent's propensity to experience shocks rather than the actual incidence of shocks.

⁴⁰The region-by-year effects have been partialled out. This is done to ensure that the trends we observe are not driven by region-specific trends that may arise because of the unequal representation of regions within distance bins.

savings behavior is only available beginning 2006. By 2008, the impact of ART is already detectable as the fraction of respondents in the “Near” group who report positive savings increases by 15 percentage points, whereas the “Far” group has a slight decrease. The right panel of Figure 3 shows the trends in total amount in savings, which again show little difference in the pre-period.⁴¹ The impact of ART is apparent by 2008, though it is much larger by 2010, which is consistent with what we should expect since savings is a stock variable.

Figure 4 shows the trends in expenditures on education per child in the past three months. The effect of ART only becomes apparent by 2010, which is consistent with what we may expect given that education decisions were likely already made by the time ART came online for the 2008 survey rounds.⁴² The right panel of Figure 4 shows very similar trends in medical spending per child in the past three months by distance group. In both graphs, we see education and medical spending are similar across groups in 2004 and continue to be similar in 2006 (consistent with the findings in Tables 1 and 2, the respondents are balanced along the distance gradient in trends and levels), indicating little evidence for differential pre-trends by distance to ART.

4.1 ART Availability and Saving Behavior

Estimates of the effect of ART availability on savings behavior appear in Table 3. We show the results using two measures of saving: if the respondent reported any savings and the total amount reported.⁴³ We find a strong and immediate response in respondents’ likelihood to save. The point estimates in column 1, indicate that reducing the respondents’ distance to the nearest ART facility by 5.8 km increases the likelihood to save by 9.2 percentage points in 2008 and 10 percentage points in 2010 over the 2006 period.

In column 2, we control for spatial controls such as proximity to any clinic, major market, major road, school, and population density, all interacted with *Post*. In column 3 we add demographic characteristics interacted with *Post*. The demographic characteristics include pre-period wealth score, age, gender, household size, marital status, education, mobile phone take-up, and roof structure. In column 4, we also include economic shocks and participation in government aid programs (also interacted with *Post*).⁴⁴

⁴¹The fraction of respondents with savings in 2006 is not statistically different by distance group, consistent with pre-characteristics analysis discussed earlier. For total amount in savings, the “Near” group does appear to have slightly more in total savings, though this is sensitive to the cutoff points.

⁴²Moreover, liquidity constrained households may need time to accumulate savings before adjusting their response for larger investments.

⁴³As many individuals report zero savings, and very few individuals report positive savings over all three survey years, we use levels in our analysis. In addition, because the distribution is heavily skewed to the right, we capped the total savings to the 99th percentile. This corresponds to a cap at US\$600, though the results are not sensitive to the threshold used. Many of the responses in this upper range are likely due to reporting error as they are frequently inconsistent with previous years’ responses and other wealth indicators.

⁴⁴Due to the large number of controls, only time-invariant controls are interacted with *Post_t*. The results are similar if we interact the controls with year dummies (Appendix Table D.3). The odd columns of this

The point estimates for respondents’ likelihood to save remain large and significant as we include controls. We also continue to see the same pattern: the share of respondents with any savings increases immediately when ART becomes available but also that the effect increases over time.⁴⁵ Due to many missing values, including the set of demographic controls sharply reduces the number of observations. The trends we observe in the point estimates are not due to the changing sample, but a result of including controls.⁴⁶

Column 5 shows that total savings also increase near ART, and the estimated effect is larger and more precise in 2010. The point estimate implies that savings would increase by 19.8 USD during 2006–10 if the respondent’s distance to ART were reduced by half, or 5.68 km. This magnitude corresponds to a 44 percent of the average savings held between 2006 and 2010. The results are robust to including spatial, demographic, and economic controls.

4.2 ART Availability and Investment in Human Capital

Estimates of the effect of ART availability on investment in human capital appear in Table 4. We show the response in spending on education, medical, and clothing for children.⁴⁷ We find that education and medical spending on children increases with ART availability, while spending on clothing appears to be unaffected. Column 1 shows results for education spending, where the coefficient on $2010 \times ART\ Proximity$ is large, 3.08, and significant; however, the coefficient on $2008 \times ART\ Proximity$ is much smaller, 0.36, and not statistically significant. The point estimate implies that reducing the distance by half would result an increase of 3.08 USD in (quarterly) spending on education per child by 2010. This increase is economically large, representing 80 percent of the average reported spending on education per child during 2004–10.

Columns 2-4 test if the results are robust to including controls. We also include a leading interaction, $2006 \times ART\ Proximity$, to test for pre-trends. The point estimates on $2010 \times ART\ Proximity$ increases to 4.51 when including spatial controls, and decrease to 3.69 when including demographic controls. Including economic shocks and participation in aid programs reduces the point estimate further to 3.22, though it is still significant at the 5 percent level. The point estimates on $2008 \times ART\ Proximity$ become larger with controls, ranging between 0.63 and 1.93, and are suggestive of an effect though they are not precisely estimated. Consistent with the findings in Table 2, the coefficient on ART

table also provide point estimates on $Post_t \times Clinic\ Proximity_i$ for all the outcomes and show that there is no effect of being near just any medical facility. Note that this exercise is analogous to another placebo test, where we would estimate the effect using the distance to clinics that do not provide ART.

⁴⁵The point estimates on $2010 \times ART\ Proximity$ are always larger than in 2008, though the difference is not statistically significant.

⁴⁶Appendix Tables D.4 and D.5 redo the estimation using the HIV-negative respondents with a balanced panel that has no missing values for the controls. While this restricts the sample size substantially, the results are similar to those presented in the main text.

⁴⁷As with total savings, we use levels for the expenditure outcomes and similarly treat the extreme upper tail of the distributions. The results are not sensitive to the threshold used. Fewer than 20 observations are affected by the cap per expenditure category. See the Data Appendix A for more details.

proximity in 2006 is always small and never statistically different from zero (in all estimates for education, medical, and clothing expenditures).

Column 5 shows results for medical spending, where the coefficient on $2010 \times ART\ Prox$ is large, 0.68 and significant; however, the coefficient on $2008 \times ART\ Proximity$ is smaller, 0.41 and significantly different from zero only at the 10 percent level. Including spatial controls increases the point estimates, as does including demographic controls, though including economic shocks reduces the point estimate somewhat. Nevertheless, we find a similar pattern as described in other outcomes: the effect of ART begins to become apparent in 2008 and increases by 2010. Unlike for education expenditures, the effect on medical spending appears to be detectable, statistically, by 2008.

We find no evidence that parents are spending more on children’s clothing. Respondents were explicitly asked not to include spending on school uniforms. Since clothing is unlikely to contribute to a child’s stock of human capital, estimating the effect for clothing expenditures provides a placebo test. If expenditures in general were increasing for reasons not related to ART, for example as a result of an income shock, then we would expect to find evidence of it in clothing expenditures (the largest category of spending on children). Column 9 shows point estimates that are small and slightly negative. Although not a precise zero, the standard errors are relatively small compared to those on the point estimates for education spending (notable since clothing is the largest expenditure parents report for children). The estimates remain close to zero as we include controls.

5 Mechanisms

This section considers possible mechanisms that may result in changes in investment when ART becomes available. We first investigate other investment and income trends to test if another economic shock is causing our results spuriously. We also explore the whether our results are driven through changing mortality patterns. Last, we use the data on perceptions of mortality risk to provide direct evidence of the expectations mechanism.

5.1 Economic Spillovers

The availability of ART may also local demand for goods and services that may indirectly affect investment. Alternatively, our findings could be the result of an income shock unrelated to ART. If respondents near ART facilities are cultivating more maize or earning more on the labor market and becoming wealthier overall then we should expect to see increases in spending in other categories as well.

The MLSFH includes expenditure data (recalled for the past three months) for key categories, including spending on the respondents’ clothing and medical needs and household spending on seed purchase, agricultural equipment, fertilizer, hired labor, funeral expenses, and medical spending on others. Labor earnings are available from 2006 onwards.

Table 5, Columns 1-8, show the effect of ART availability on various expenditures mea-

sured in levels.⁴⁸ The point estimates are small, and in some cases negative, though generally imprecisely estimated. If anything, there appear to be reductions in spending for others’ medical spending and hired labor, though these are only marginally significant. The reduction in medical spending for people other than the respondent or the respondent’s children, and the reduction in hired labor are consistent with ART reducing the caretaking burden and dependency ratio (see below). We also find reductions in spending on fertilizer, which is somewhat counterintuitive since it may be viewed as an investment. However, fertilizer is a short-term investment, especially relative to long-term investment such as children’s human capital.

Columns 9 and 10 show total (non-child) expenditures and labor earnings in logs.⁴⁹ For log-expenditures and log-earnings, we restrict the estimation to individuals with strictly positive values for all years. While this approach restricts the number of observations (by approximately 15%), it reduces the bias associated with an unbalanced panel and can be interpreted as the effect of treatment at the intensive margin.⁵⁰ Column 9 shows that overall non-child expenditures are decreasing nearing ART, which is consistent with the idea that households are substituting away from short-term investment in favor of long-term investment, e.g. savings and children’s human capital.

Column 10 shows that respondents near ART do not report higher annual earnings (the point estimate is small and slightly negative). We also consider the effect of ART on the overall wealth index (roughly mean 0, standard deviated 2) calculated using PCA incorporating all reported assets, housing structure, expenditures, land, animals, and crop yield, shown in Column 11. While the wealth index includes some outcomes that respond positively to ART, we should not expect the overall wealth of households to improve substantially in the short-run as a result of ART since increased savings and long-term investment should only increase future wealth. We find that the point estimates are slightly negative (corresponding to about 0.03 standard deviations) and insignificant in all years, including in the pre-ART period. The estimates for all expenditures, wealth, and earnings indicate that our main results are not driven by an income or productivity shock.

Since overall expenditures appear to be increasing (due to child investments) and respondents report to have more in savings, for budgets to balance, households must be decreasing other expenditures or increasing labor supply on their own farms.⁵¹ We show here that there is some evidence that overall non-child expenditures are decreasing. Additionally,

⁴⁸Because of frequent zeros, the estimates for these categories use levels (in USD), treating outliers in the same way as described for expenditures on children.

⁴⁹Log of total expenditures is the log of the sum of individual expenditures in Columns 1-8 of Table 5. If we include expenditures on children (school, medical, and clothing), then we find that overall expenditure is increasing as a result of ART. The point estimate implies an elasticity (with respect to distance to ART) of 0.29 and is significant at 10%.

⁵⁰The (null) results are not sensitive to this specification, as the regressions in levels yields small and imprecise point estimates.

⁵¹In theory, individuals may also borrow, though in our setting households are liquidity constrained.

ART availability is associated with improvements in labor supply, as measured by time spent working on the farm (Baranov, Bennett, and Kohler 2012). These results are consistent with the life-cycle model, since investment and labor supply are jointly determined. As individuals increase savings and investment in long-term assets, they must adjust either by reducing expenditures in non-long-term assets or increasing labor supply, or both.⁵²

5.2 Mechanical Effects of Reducing Mortality

We first rule out the possibility that the results are driven by the direct effect of HIV-positive respondents receiving the life-saving medication by showing that the results are robust to excluding the HIV-positive sample.⁵³ However, there are other important channels by which ART can impact investment without changing expectations. One possible effect of ART availability is that family members other than the respondent who were ill with AIDS began receiving treatment. This would reduce the burden of taking care of a sick household member.⁵⁴ Additionally, because AIDS mostly affects individuals during their most productive age, the sickness and death from AIDS reduces the number of productive members in the household.

Another related effect of ART is a reduction of orphaned children. Orphaned children would often be sent to live with neighbors or extended family, increasing the number of dependents in the household. Such a shift in the household structure increases the caretaking burden and may decrease investment in human capital for even the non-orphaned children. While the total number of orphans may not be large enough to fully explain changes in school enrollment due to changes in life expectancy, the effects of orphanhood may be amplified through their effects on households that care for them. Indeed, in Sub-Saharan Africa, about 20% of households have an orphan living with them (Evans and Miguel, 2007). Since our results are estimated using the same individuals over time, we do not capture any changes in schooling for orphans themselves. However, households near ART may be less likely to

⁵²Baranov, Bennett, and Kohler (2012) also find improvements in mental health associated with reduction in worry about AIDS mortality, suggesting that the increased labor supply may be driven by improvements in mental health. While the patterns of expenditures do not support that our findings are driven entirely by mental health improvements (as that would be akin to a productivity or income shock), it is possible that large reductions in mortality risk increase investment through the horizon effect but also reduce anxiety and stress, improving mental health, which somehow translates to increased productivity or effort. However, there is still no theoretical grounding to support the mental health mechanism, as the role of mental health in economic decision-making is still poorly understood.

⁵³Some individuals did not consent to the HIV test, or others were not reached by the HIV testing team during the 2004–08 MLSFH rounds. As a result, 17% of our sample did not have HIV testing results by 2008. The results are also robust to restricting the sample to only HIV-negative respondents (see Appendix Tables D.4 and D.5). The survey did not conduct HIV testing in 2010, so we are unable to exclude individuals who seroconvert between 2008 and 2010. These individuals would be unlikely to start treatment since a maximum time from infection of two years is generally too short to develop the clinical symptoms to be eligible to start ART (based on local eligibility criteria).

⁵⁴This channel may be potentially large: In South Africa, where a similar ART rollout occurred over a similar time period, Bor et al. (2011) estimate that 25% of the population shared household or compound membership with someone who initiated ART by 2010. However, the HIV prevalence in KwaSulu-Natal was much higher, at 20% of adults.

receive AIDS orphans after ART becomes available than those who live far.

Table 6 explores whether the mechanisms described above are driving our main results. Panel A estimates the effect of ART availability on savings and investment outcomes excluding the HIV-positives (the remaining panels also exclude HIV-positives). The point estimates for savings outcomes are very similar to the baseline results. The point estimate for expenditures on children’s education is reduced by 27 percent from the baseline specification, which indicates that the HIV-positives were also differentially spending more on children’s education near ART.⁵⁵

Panel B restricts the sample to respondents that reported no AIDS-related deaths in the household in the previous two years in all waves of the survey. The questionnaire specifically asks if the death is suspected to be AIDS-related. Because the stigmatization of AIDS may lead to an underreporting of AIDS deaths, we also include any deaths that reported the age of the deceased between 15 and 49 as the large majority of these deaths are caused by AIDS. Panel C excludes respondents who ever reported a seriously ill household member. The results from Panels B and C show that point estimates are similar, though somewhat less precise when excluding deaths or illnesses in the household. The total amount in savings results were also weaker for these groups. Last, to proxy for the presence of orphans, Panel D excludes respondents who ever reported non-biological children co-residing with them.⁵⁶ The results are similar for all outcomes, but we do find a substantial reduction in the point estimate on education expenditures, with the point estimate for $2010 \times Proximity$ at 1.78, and not statistically different from zero. There is some evidence that the estimates are picking up mechanical effects. However, the overall results remain consistent with the baseline estimates for the HIV-negative sample, suggesting that main driver for our findings is expectations.⁵⁷

5.3 Subjective Expectations

Table 7 reports the estimates for the effect of ART availability on 5-year subjective mortality risk.⁵⁸ Column 1 shows the results using the full sample and column 2 excludes respondents

⁵⁵The results for the HIV-positive sample indicate that they are also increasing investment behavior, though the estimates are imprecise due to the small sample.

⁵⁶Weinreb, Gerland, and Fleming 2008 identified orphans in the MLSFH data more precisely, but our approach is more conservative and thus preferable here.

⁵⁷The reason we find little effects of caretaking is likely because of the number of households with HIV-positive individuals who become sick with AIDS is quite low in the cross-section and would change little between 2008 and 2010 (because the HIV prevalence was about 8% in rural Malawi, and of those that are HIV+ and become sick enough to be eligible for treatment over the 2 years is substantially smaller due to the slow progression of the disease). Over longer time periods, the mechanical effects of reducing illness, death, and orphans should become evident.

⁵⁸It is noteworthy, however, that MLSFH respondents have exaggerated perceptions of their mortality risk. Although the life-table mortality risk estimate over five years for people aged 35–40 is 10 percent, respondents perceive a 39 percent risk of death. This overestimation of mortality is likely due to the high prevalence of AIDS-mortality at the time (MLSFH respondents also have a median of two acquaintances who are sick with AIDS and know two others who have died of AIDS in the past year), and the social importance of funerals (MLSFH respondents, for example, attend a median of three funerals per month).

who ever tested positive for HIV. The point estimates imply that reducing distance to ART by half would reduce respondents' 5-year mortality risk by 0.058 (0.057 for the HIV-negative sample) by 2010. The nonparametric estimates are presented in Appendix Figures D.4. We use these point estimates to calculate the implied life expectancy gain using mortality tables (outlined in the appendix). The magnitude of the implied subjective life expectancy gain from reducing the distance to an ART facility by 5.8 km is approximately 6.8 years.

Large differences in HIV prevalence exist between men and women in Malawi. In our sample, HIV prevalence in 2006 among women was 4.4 percent versus 2.8 percent in men.⁵⁹ Moreover, AIDS mortality for women occurs earlier in life than for men because women are infected at younger ages.⁶⁰ The combination of higher prevalence and earlier infection implies that the life expectancy gains from ART are substantially larger for women.⁶¹ These differences are reflected in the subjective mortality risk response of MLSFH respondents. Table 7, columns 3 and 4 show the results for subjective mortality risk for women and men, respectively. The point estimate on the 2010 coefficient shows that ART availability decreases mortality risk for women by 0.064, and for men by 0.045. These point estimates correspond to implied life expectancy gains of 8.5 and 6.2, respectively.

Another limitation we have is that we observe subjective mortality for respondents but not their children. It may be the case that adults believe that their children will have access to treatment regardless of location. Unfortunately, we do not directly measure parents' beliefs about their children's mortality risk. As an indirect measure, we estimate the change in subjective mortality risk for the youth sub-sample in column 5 of Table 7. The results are large and significant, despite the small sample size, indicating that there does not seem to be a generational gap in the effect of ART availability.

Finally, we should expect that the effect of ART is larger for those respondents who report higher likelihoods of being infected at baseline. Column 6 shows the differential effect of ART for individuals who are HIV-negative, but report a positive subjective probability of being infected in 2006. We define HIV Risk equal to 1 if individuals reported positive probability of being infected in 2006, approximately 30% of the HIV-negative sample. The

In addition, individuals in Malawi received signals about mortality risk from public information campaigns, many of which discourage risky behavior through stark messages about the danger of HIV/AIDS (e.g., [Jato et al. 1999](#); [Gupta, Katende, and Bessinger 2003](#); [Geary et al. 2007](#)). Despite this overestimation of the level, the MLSFH subjective mortality expectations adequately reflect gradients in mortality gender, age, education, and region of residence, and variation in mortality perception among MLSFH respondents are likely to reflect true underlying differences in subjective survival probabilities ([Delavande and Kohler 2009](#)).

⁵⁹These estimates are low because we restrict our sample to maintain a balanced panel. For the unrestricted sample, the 2006 prevalence was 6.9% (women) and 3.9% (men). 2010 DHS estimates for rural Malawi are 10.5% (women) and 7.1% (men) [Malawi DHS \(2011\)](#), with the lower prevalence in the MLSFH population due to the fact that the MLSFH does not include peri-urban areas with higher HIV prevalence that are included in the DHS rural sample [Kohler et al. \(2014\)](#).

⁶⁰The difference in prevalence can partly be explained by transmission probabilities. Furthermore, the distribution of HIV prevalence by age is shifted left for women. A common explication of this phenomenon is that younger women date older men because they are wealthier.

⁶¹UN life tables suggest that the estimated life expectancy gains from eliminating AIDS mortality are 11.1 years for men, compared to 14.4 years for women.

specification is a triple-difference, controlling for HIV Risk interacted with year dummies.⁶² The coefficients suggest that the effect of distance were initially driven by the high risk group, the coefficient on the triple interaction in 2008 is -0.07 and significant, while the overall effect of distance is small and insignificant. By 2010, the effect of ART is similar for those in the high risk and low risk groups. Because this specification controls for baseline HIV Risk interacted with year dummies, it also tests whether mean reversion drives our results.⁶³

6 Life Expectancy and Schooling

Our results thus far suggest that ART availability resulted in increased spending on children’s human capital by way of changing perceptions about longevity. To further strengthen this conclusion, we also estimate the effect of ART availability on children’s grade attainment as reported by their parents. Given frequent school interruptions and grade repetition in context such as rural Malawi, highest attained schooling grade is generally a better indicator of a child’s human capital than years of schooling.

Table 8 provides results using the sample of respondents’ children who are of school age (5–19) and are reported in the 2006, 2008, and 2010 years of the survey. We chose to use grade completion (and control for age interacted with year in all regressions) rather than grade-for-age for ease of interpretation, although using grade-for-age yields similar results. Including spatial and demographic controls slightly increase the point estimates on grades completed. The effect of ART on grade completion seems to be quite large. The point estimate in column 1 implies that decreasing the distance to ART by half would increase years of schooling by 0.25 in the full sample, and the estimate increases to 0.33 in the sample excluding HIV-positive parents (column 2). The effect is only large and significant by 2010, which is consistent with the lagged response of educational spending. The results are robust to including spatial and demographic controls (see Appendix Table D.6 and D.7).⁶⁴

Isolating the Horizon Effect

Since ART increases life expectancy for adults and children, the results presented in Table 8, columns 1 and 2, include the effect of life expectancy gains for parents and children. However, we wish to calculate the implied effect of an additional year of children’s life expectancy

⁶²As women are more likely to be in the high risk group, we also control for gender-year effects.

⁶³Since subjective mortality risk and subjective infection risk were not balanced at baseline, we worry that our results may be driven by mean reversion. Our results throughout are robust to including baseline HIV risk interacted with year dummies, suggesting that our results are not simply due to mean reversion (available from the authors upon request).

⁶⁴We also find evidence of improvements in child health. Theory predicts that parents expecting to live longer should invest in their children’s health, because it will enable them to earn higher wages as adults. Appendix Table D.6, cols 4-6, show that by halving the distance to ART, parents are 12 percentage points more likely to report their child to be in excellent health by 2008 and 14 percentage points by 2010 (those percentages are 14 and 15, respectively, when excluding HIV-positive parents). Including spatial and demographic controls reduces the point estimates slightly, but substantially decreases the precision.

on schooling to estimate the horizon effect outlined in human capital theory (Ben-Porath 1967).⁶⁵ To estimate this effect of children’s life expectancy on years of schooling without capturing the effect of parental longevity, we exploit differential life expectancy gains by gender.⁶⁶ We use a triple-difference model to estimate the additional increase in grade attainment girls received relative to boys as a result of ART:

$$y_{it} = \beta \text{Girl}_i \times \text{Post}_t \times \text{Proximity}_i + \gamma \text{Girl}_i \times \text{Post}_t + \eta \text{Post}_t \times \text{Proximity}_i + \alpha_i + \delta_{rt} + \varepsilon_{ijt}.$$

We include age-by-year effects, individual fixed effects and region-year effects and allow individual indicators for 2010 and 2008 instead of *Post*. As in the rest of the paper, the standard errors are clustered at the village level, *j*. The individual fixed effect absorbs the control for gender and ART proximity, as both are time invariant, and the region-by-year effects absorb the control for *Post*.⁶⁷

Columns 3 and 4 show the differential impact of ART availability by girls and boys in a triple difference regression. The point estimates on the triple difference are not precise. We also include results for a restricted sample of only older children, since the younger children may not have yet had a chance to drop out. These results give slightly higher estimates and are significant at the 10% level. Although the standard errors are large (potentially because of the limited sample size), they are robust to including various controls (see Appendix Table D.7). The estimates suggest that girls’ schooling attainment increases by 0.38 years more than for boys. Given that the life expectancy gains for girls are 3.3 years greater than for boys, we can divide these numbers to get a “back-of-the-envelope” estimate of the effect: These results imply that the marginal effect of an extra year of life expectancy on years of schooling is 0.08 (or 0.12 using the results for the older children).⁶⁸ The magnitude of the effect is very similar to that estimated by Jayachandran and Lleras-Muney (2009), and more recently by Hansen (2013).

⁶⁵ If ART only increases life expectancy for the respondents but not their children, the rate of return to education from the perspective of the child is not affected. However, the parents are now more likely to live into old age and receive benefits from investments in child human capital through upward intergenerational transfers (Banerjee 2004). Holding fixed the life expectancy of the parents, when children are expected to live longer, the rate of return to education from the perspective of the child has increased. Therefore, since ART increases life expectancy for adults as well as children, there are two relevant margins that push toward higher investment in human capital.

⁶⁶This approach is similar to that of Jayachandran and Lleras-Muney (2009).

⁶⁷This model implies the assumption that parents are not more likely to invest in girls versus boys for reasons other than their different life expectancy gains. We look for evidence of a gender bias in educational attainment before ART is introduced in the children’s sample and the youth respondents. If anything, boys have slightly higher grade attainment.

⁶⁸This calculation is biased downward as we attribute the change in grade attainment, which is estimated using the distance gradient, to the full difference in life expectancy gains.

7 Conclusion

While economic theory predicts that a longer life expectancy increases the value of long-term investments such as education, it has ambiguous predictions for saving behavior. Recent studies provide compelling evidence suggesting that education responds to life expectancy; however, few studies have considered the effects on savings. This paper uses spatial and temporal variation in the availability of life-extending AIDS medication to evaluate its impact on savings and human capital investment in Malawi. Our study has several advantages: it allows us to estimate the effects of ART on the savings behavior and human-capital investments of HIV-*negative* individuals, that is, individuals who do not directly benefit from receiving ART. In addition, we use data on self-reported mortality risk to provide direct evidence that individuals actively change investment decisions based on their subjective longevity.

We employ a difference-in-difference strategy to estimate the impact of ART availability on savings, education expenditures, and children's schooling. The identification strategy compares the investment outcomes of people who live near and far from ART, before and after it became available.

We find large effects of ART availability on reported savings and investment in children's human capital. Consistent with these findings, we also show that ART availability improves educational attainment for children of the respondents. For example, halving the distance to ART (a decrease of approximately 5 kilometers for the average respondent) would imply an increase in schooling by 0.3 years. The results are similar for the HIV-negative respondents, indicating that the results are not driven by the direct effect of HIV-positive individuals receiving life-saving medication. Other potentially important channels not related to changing expectations, such as the household caretaking burden from AIDS-related illness, death, and orphanhood, cannot explain our findings. However, ART availability does have a measurable decrease in self-reported mortality risk.

Taken together, these results suggest that our findings are due to changes in expectations about longevity, and provide compelling evidence in favor of the mechanism in human capital theory. The savings results also provide evidence that higher life expectancy does prompt more savings.

Our findings also have important policy implications. We show that antiretroviral therapy leads to large and economically important increases in savings and investment behavior both for HIV-positive and for healthy individuals. This spillover benefit should be incorporated into cost-benefit analyses of such programs by governments and donor organizations. Our results also suggest that the impact of ART may have large implications for economic growth in sub-Saharan Africa.

$N = 1379$. For child sample (Panel D), $N = 525$. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Note: This table describes characteristics of respondents and their children in 2006, before ART became available. Columns (3) and (4) report the coefficient on ART proximity (parameterized as the negative log distance) from regressing each variable on ART proximity and stars indicate significant coefficients. Column (3) only controls for region dummies, while column (4) controls for spatial characteristics (described in detail in the text). The sample of survey respondents is restricted to those who were interviewed in all three years for the main analysis (2006, 2008, and 2010). Panel D describes characteristics of the respondents' children and is restricted to children who were reported in the household roster for all three years.

Table 2 – Pre-ART Trends: Changes between 2004–2006

Shocks & aid programs	–	–	–	Yes	–	–	–	Yes

* $p < .10$, ** $p < .05$, *** $p < .01$

Note: Standard errors (in parentheses) are clustered by village and robust to heteroskedasticity. ART proximity is parameterized as the negative of log distance by road. All regressions include individual fixed effects and region-by-year dummies. The sample is restricted to individuals who were interviewed in all three years of the survey (2006, 2008, and 2010). Spatial controls include population density and proximity to clinic, market, major road and school (interacted with $Post_t$). Demographic controls include pre-period wealth, roof material, if the respondent has a mobile phone, age, household size, gender, education, and marital status (interacted with $Post_t$). Controls for economic shocks and other aid programs are described in detail in the text.

Table 4 – ART Availability and Expenditures on Children

Dependent variable:	Education (USD)				Medical (USD)				Clothing (USD)

Shocks & aid programs	–	–	–	Yes	–	–	–	Yes	–	–	–	Yes

* $p < .10$, ** $p < .05$, *** $p < .01$

Note: Standard errors (in parentheses) are clustered by village and robust to heteroskedasticity. ART proximity is parameterized as the negative of log distance by road. All regressions include individual fixed effects, region-by-year dummies, and month of interview controls. The sample is restricted to respondents with school-age children and regressions are weighted by inverse of number of household respondents. All regressions use data from 2004. Spatial controls include population density and proximity to clinic, market, major road and school (interacted with $Post_t$). Demographic controls include pre-period wealth, roof material, if the respondent has a mobile phone, age, household size, gender, education, and marital status (interacted with $Post_t$). Controls for economic shocks and other aid programs are described in detail in the text.

Table 5 – ART Availability, Income, and Other Expenditures

Mean of Dep. Variable	9.56	1.92	0.87	1.25	0.67	0.88	5.38	4.87	2.68	4.46	0.21

* $p < .10$, ** $p < .05$, *** $p < .01$

Note: Standard errors (in parentheses) are clustered by village and robust to heteroskedasticity. ART proximity is parameterized as the negative of log distance by road. All regressions include individual fixed effects, region-by-year dummies, and month of interview controls. The sample is restricted to individuals who were interviewed in all three years of the survey (2006, 2008, and 2010). Estimates for columns 1,2, 4-8, and 11 also use data from 2004. Because of frequent zeros, the estimates in columns 1-8 use levels of total spending as the dependent variable. For estimates in columns 9 and 10, only respondents with positive values of expenditures and earnings in all years were used. The outcome variable in column 11 is a total wealth index (roughly mean 0, standard deviated 2) calculated using PCA incorporating all assets, housing structure, expenditures, land, animals, and crop yield.

Table 6 – ART Availability and Investment – Mechanisms

Dependent variable:	Saving Behavior		Expenditures on Children (USD)

Observations	1578	1521	1521	1368
Within R2	0.69	0.69	0.69	0.69
Mean of Dependent Variable	3.68	3.70	3.70	3.94

* $p < .10$, ** $p < .05$, *** $p < .01$

Note: Standard errors (in parentheses) are clustered by village and robust to heteroskedasticity. ART proximity is parameterized as the negative of log distance by road. All regressions include child fixed effects and region-by-year dummies. The sample is restricted to children who were reported in all three years of the survey (2006, 2008, and 2010). Regressions are weighted by inverse of number of children per household. Except for column 1, regressions exclude children whose parents ever tested positive for HIV. Columns 3 use the full sample of children aged 5-19, and column 4 only includes children who were older than 12 years old by 2010.

Appendix: For Online Publication

A Data Appendix

A.1 Data Sources and Sample

Malawi Longitudinal Survey of Families and Health (MLSFH):

Our analysis uses data from 4 waves of the MLSFH: 2004, 2006, 2008, and 2010.⁶⁹ The MLSFH collected GPS coordinates of households in 2004, and the survey team also conducted HIV testing in 2004-2008 waves of the survey. Figures 1 and D.1 show the distribution of spatial characteristics and location (within the circle) of respondents for each region of the survey.

- *Sample selection:* Our results are estimated using the set of respondents that are present for all three years of the survey from 2006-2010, though the results are similar using the entire sample of respondents. For regressions with 2004 data, we use the available data for those respondents that were interviewed in 2004, but still include the respondents that have missing data in 2004. This is done to maximize the sample size using the full set of outcomes of interest that are available (since savings, earnings, and subjective expectations were only added to the survey module beginning 2006). The results using a balanced panel starting with 2004 are show in Appendix Tables D.4 and D.5.
- *Treatment of outliers:* All variables of monetary values, such as total savings, expenditures on education, expenditures on clothing and so on, are in levels. Values for extreme outliers were capped, though this affects a small number of observations (fewer than 2%). For example, the cap for savings was at US\$600, though the results are not sensitive to the threshold used (the point estimates increase with the cap). Many of the responses in this upper range are likely due to reporting error as they are frequently inconsistent with previous years' responses and other wealth indicators. Alternatively, dropping individuals who ever reported wildly inconsistent values (that is, those ever effected by the cap) also does not effect our results. We have also performed the analysis by windsorizing that data at varying percentiles. The results are robust to changing the percentile (e.g. 99th, 95th, etc).

⁶⁹This survey has also been referred to as the Malawi Diffusional and Ideational Change Project (MDICP) in the past. With major data collection rounds in 1998, 2001, 2004, 2006, 2008, 2010, and 2012 for up to 4,000 individuals, as well as ancillary surveys and qualitative studies, the MLSFH has been a widely-used dataset for research on health, family dynamics, social networks, and HIV infection risks in a rural SSA context (Kohler et al. 2014).

MLSFH Child Sample

For the child sample, we use data constructed from household rosters (the linkage process was done by [Castro, Behrman, and Kohler \(2014\)](#)). The MLSFH household rosters do not provide unique identifiers for each person who is listed by the respondent on the household roster that was collected during the 2006-10 MLSFH surveys. To allow for longitudinal analyses of the information elicited in these household rosters, the data on the respondent's children listed in the 2006, 2008 and 2010 MLSFH household rosters were linked using names, ages, sex, and birth order. Because not all data were available in every wave, and because the spelling of names is not always exactly identical across waves, the matching was not undertaken with a computerized algorithm, but was done case-by-case instead. Two processes were undertaken simultaneously. First, names were designated the principal matching variable; so to be considered matched, a minimum similarity in spelling was required. Second, a quality indicator for the quality of the match was assigned to each matched child, with the match being *low quality*, if no other data than the spelling itself was available to establish the match, and the spelling itself was not sufficiently similar across waves, *medium quality*, if any other variable was available (age, sex, birth order) to establish the match or, if no other data was available but the spelling matched very closely, and *high quality*, if two or more variables were available to establish the match. Only children of medium and high quality of match are included for the analyses of this paper, which represent about 90% of the total matched cases. See [Castro, Behrman, and Kohler \(2014\)](#) for additional detail of this linkage process.

Spatial Data

All spatial analysis was performed using ArcGIS. Distance calculations were computed using ArcGIS Network Analyst.

- *Clinic Data, HIV Unit at the Malawi Ministry of Health:* We obtained data on ART start dates, GPS coordinates, and other clinic characteristics from the HIV Unit at the Malawi Ministry of Health. Clinic database with GPS coordinates did not contain ART service start dates, but a separate list of clinics providing ART with start dates was obtained from the HIV Unit and matched by hand to the clinic database.
- *Road Network Data, Malawi National Statistics Office (NSO):* In order to determine distance by road, we incorporate road network data (arcGIS files) provided by the Malawi National Statistics Office (NSO). The NSO data also contained coordinates of important landmarks such as schools and trading centers.
- *Population Density, Afripop data:* We use estimated population density at a resolution of 100 meters from the Afripop database.

A.2 Attrition Analysis

Appendix Table D.1 provides summary statistics by attrition status and shows significant differences between attritors and non-attritors. Attritors tended to be younger, male, unmarried, more educated, closer to major roads, and more likely to be HIV-positive. As described in the data section above, we estimate Equation 3.1 using a balanced panel. Thus our results are internally valid (even if there is attrition) as long as attrition is not correlated with ART proximity. We worry that individuals who live far from ART and are forward-looking may move closer to ART facility (and attrit from the sample). Thus the sample of respondents that remain in the analysis would include both types (forward-looking and not) in the near areas and only present-biased types in the far areas. Several pieces of evidence suggest this is not the case. First, attrition is not correlated with ART proximity, which can also be seen in Table D.1 as the “Distance to ART in 2008” (Panel E) in columns 1 and 2 are not statistically different (if anything attritors were closer to ART facilities). Second, attritors did not appear to be less present biased, there is no difference in whether the respondent exhibited a “High discount rate” (Panel B) by attrition status.

Appendix Table D.1 also repeats the balancing tests (regressing characteristics on ART proximity controlling for spatial characteristics) for the attritor sample. Among attritors, people near ART were more likely to be HIV-positive and report more sick relatives that died of AIDS. Attritors near ART also had more education. And they were more likely to have a mobile phone, a pattern that also appeared with the non-attritors. However, there was balance in the main outcomes of interest (Panel D), even among attritors.

B Theoretical Predictions

This section briefly describes the theoretical predictions for the effect of increasing life expectancy on savings and human capital investment.⁷⁰ First, we discuss how life expectancy gains may influence savings in models of life-cycle savings, precautionary savings, and savings for investment in a credit constrained environment.

In the life-cycle model of savings, increasing longevity implies that individuals are more likely to live into old age when income is low, thereby increasing motivation to save (Bloom, Canning, and Graham 2003; Freire 2004; Lee, Mason, and Miller 2000; Zhang and Zhang 2005). However, improvements in longevity are often associated with reductions in morbidity, lengthening the working life and reducing the need to save (Fogel 1994, 1997). The implications on saving also depend on the prevailing life-cycle patterns of production and consumption (Lee and Mason, 2011; Deaton, 1989), and may be very different in countries with little old-age dependency (as is the case in low income SSA countries) as compared to countries with extended periods of old-age dependency.

⁷⁰In addition, life expectancy also plays a role in decisions about fertility (Fortson 2009; Shapira 2010) and labor supply (McLaren 2010).

Precautionary savings are another motivation for saving, particularly in developing countries.⁷¹ For example, individuals may hold savings in anticipation of future illness, funeral costs, or bequests (Van de Kuilen and Lammers 2007; Freire 2004). If individuals were saving to insure themselves against an AIDS-related shock, then precautionary savings may decrease when ART becomes available. On the other hand, individuals may be more likely to save if those savings were to go toward procuring ART.⁷²

Lastly, individuals may be saving to self-finance investments when credit is not available (Fafchamps and Pender 1997). Since long-term investments become more attractive when longevity rises, liquidity-constrained individuals may increase savings in order to finance these investments.

Individuals may save for any combination of reasons described above, thereby making it difficult to *a priori* predict the effect of a life expectancy increase on savings.

C Effect of ART on Subjective Life Expectancy

In this section, we calculate the implied effect on subjective life expectancy (SLE) from the estimates on 5-year mortality risk reported in Section 5.3. Using the estimates of the impact of ART availability on subjective mortality risk as the first-stage is a valid approach if our identification strategy was only picking up the effect expectations. The implied subjective life expectancy is calculated by adjusting the age-specific mortality rates from life tables.⁷³ Based on that calculation, we report the effect of ART availability on subjective life expectancy. We can then compare the effect on subjective life expectancy to estimates of actual life expectancy gains from eliminating AIDS mortality.

The life tables provide age-specific mortality rates in 5-year increments (e.g., mortality rate for the age group 20-24). To estimate the implied life expectancy gain, we adjusted the age-specific mortality rates between the ages of 15 and 49 (this is generally the age range for which HIV prevalence is reported), although the calculation is not particularly sensitive to extending the mortality decreases beyond 49 (to, say, 69). The estimated effect on 5-year mortality risk from our respondents is an average based on all respondents and is not age-specific. While it would be possible to estimate the effect of ART on 5-year mortality risk for each age group, the estimates become less precise. Thus we use the overall effect of ART on 5-year mortality risk to adjust the age-specific mortality rates in the age groups where AIDS mortality is occurring.

We take two approaches in interpreting the bean measure as a probability. In the first, we assume that the level change in subjective mortality risk reported using beans is an accurate

⁷¹In general, it is not clear that an increase in life expectancy should have an effect on precautionary savings.

⁷² While the medication itself is free, there are additional costs of food and care during the time the patient recovers once they start treatment.

⁷³We use life tables from the UN Population Division for Malawi in 2009 since these are calculated based on mortality data the 5 years prior, which corresponds best to the years of the survey.

reflection of the respondents' risk assessment. In this case, we apply the 5.8 percentage point decrease to the relevant age categories.⁷⁴ The second approach assumes that the level of mortality risk that individuals report does not reflect their true beliefs, but that the percentage change over the level is meaningful. Then 5.8 percentage points more accurately reflects a 15 *percent* decrease in mortality risk (since the average perceived mortality risk before ART was 0.39). We do this second approach because we may be concerned with interpreting the response in levels, given the levels of perceived mortality risk are high as compared to life-table based estimates of mortality risks (Delavande and Kohler, 2009) seem implausibly high. We then apply a 15 percent decrease to the 5-year death probabilities to the relevant age categories in the life tables. These two approaches yield different results: the first approach using levels implies a life expectancy (at age 5) gain of 6.8 years, whereas the second approach implies a life expectancy gain of 4.2 years. We should note that these subjective life expectancy gains are estimated off of the distance gradient, and should be interpreted as the effect on SLE when moving ART 5.8 km closer to the respondent.

We can compare these subjective life expectancy gains to the estimated life expectancy gains of eliminating AIDS in Malawi (UN World Population Prospects, 2010 Revision). According to these estimates, eliminating all AIDS mortality in Malawi would lead to an increase in observed life expectancy of 12.7 years. The gains provide a reasonable upper bound for the effect of ART on subjective life expectancy, since ART medication does not entirely eliminate AIDS mortality.⁷⁵ In light of the large change in objective risk, the strong response in subjective mortality risk and other behavior changes among the HIV-negative sample does not seem implausible.

⁷⁴Except for the 15-24 age groups, which we treat separately, since that would result in negative mortality probabilities. Here we smooth the values by interpolating the decrease in mortality risk linearly.

⁷⁵The life expectancy gains may seem high given the prevalence of HIV. It is useful to realize that the lifetime risk of getting HIV is also much higher than the prevalence, and in a country with 10 percent prevalence the lifetime risk of HIV is approximately 45 percent (Blacker and Zaba 1997).

D Appendix of Graphs and Tables

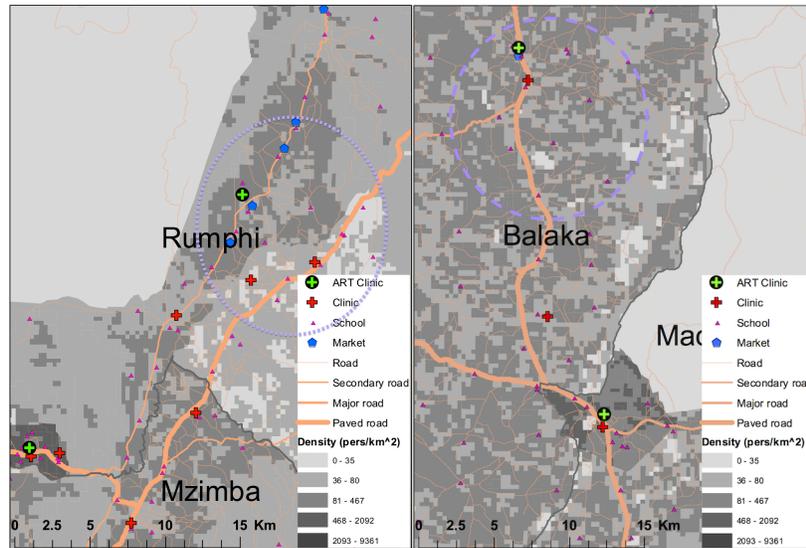

Figure D.1 – Geography of Other Regions

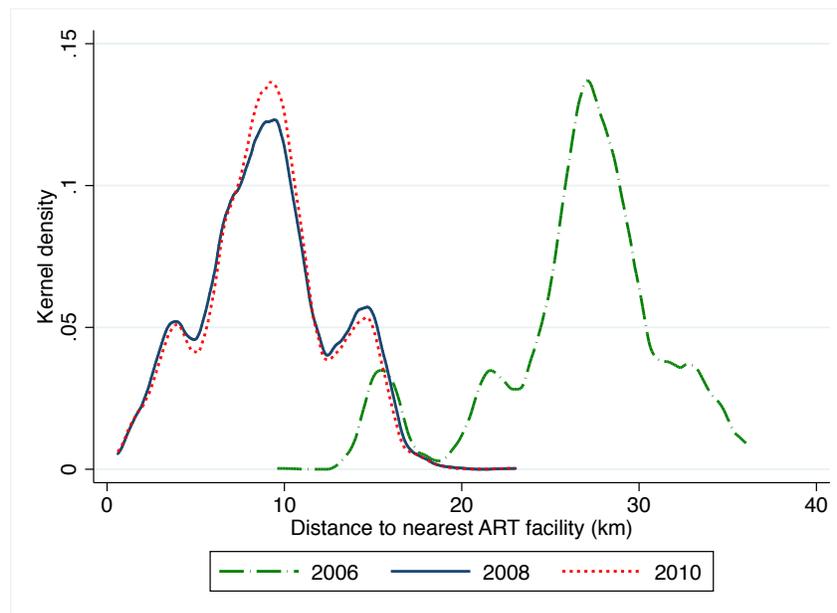

Figure D.2 – Distribution of distances to ART by year

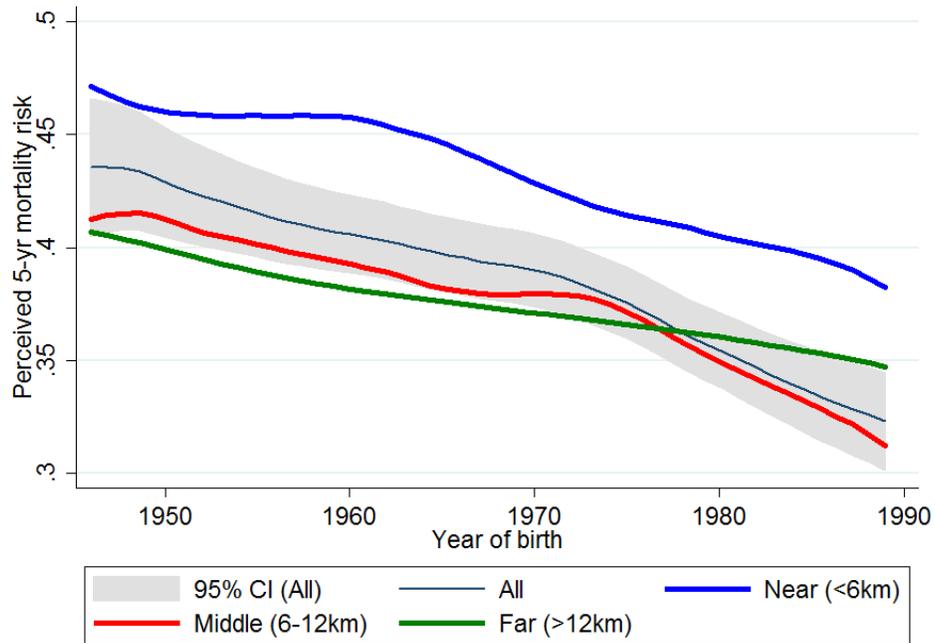

Figure D.3 – Subjective Mortality Risk in 2006 by Year of Birth

Notes: This figure plots local linear estimates of subjective mortality risk in 2006 as a function of birth cohort. Region effects have been partialled out. Standard errors are not clustered or adjusted for the two-stage estimation, so they are only shown as guide. Since this graph represents a pre-trend test, standard errors that are downward biased represent a conservative approach, as we are more likely to reject the null, leading us to conclude that there were differential pre-trends. Even so, the results do not suggest that trends were diverging prior to ART.

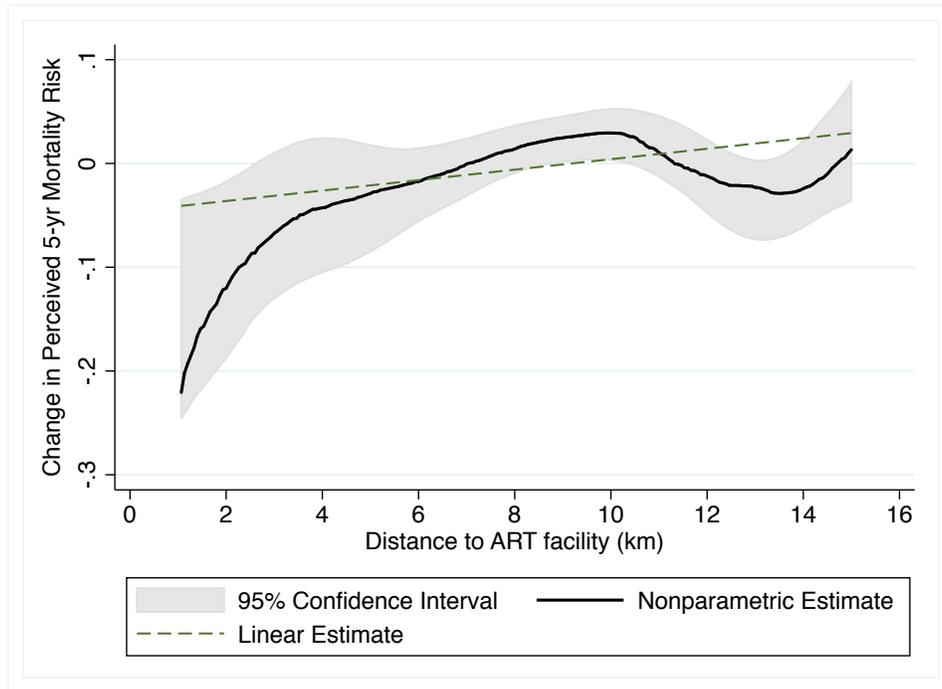

Figure D.4 – Change in 5-year subjective mortality risk by distance to ART

This figure shows nonparametric estimates of changes in the subjective mortality risk by distance to ART. Changes are computed using 2010 as the “post” year, and 2006 as the “pre” year. This corresponds to the coefficient on $2010 \times ART\ Proximity$ in the parametric results presented in the tables. All graphs are nonparametric local linear regressions with region-year effects partialled out. Confidence bands at the 95% are computed using 1,000 bootstrap replications, clustered by village. In each bootstrap step, and undersmoothed local linear bandwidth is chosen following [Hall \(1992\)](#).

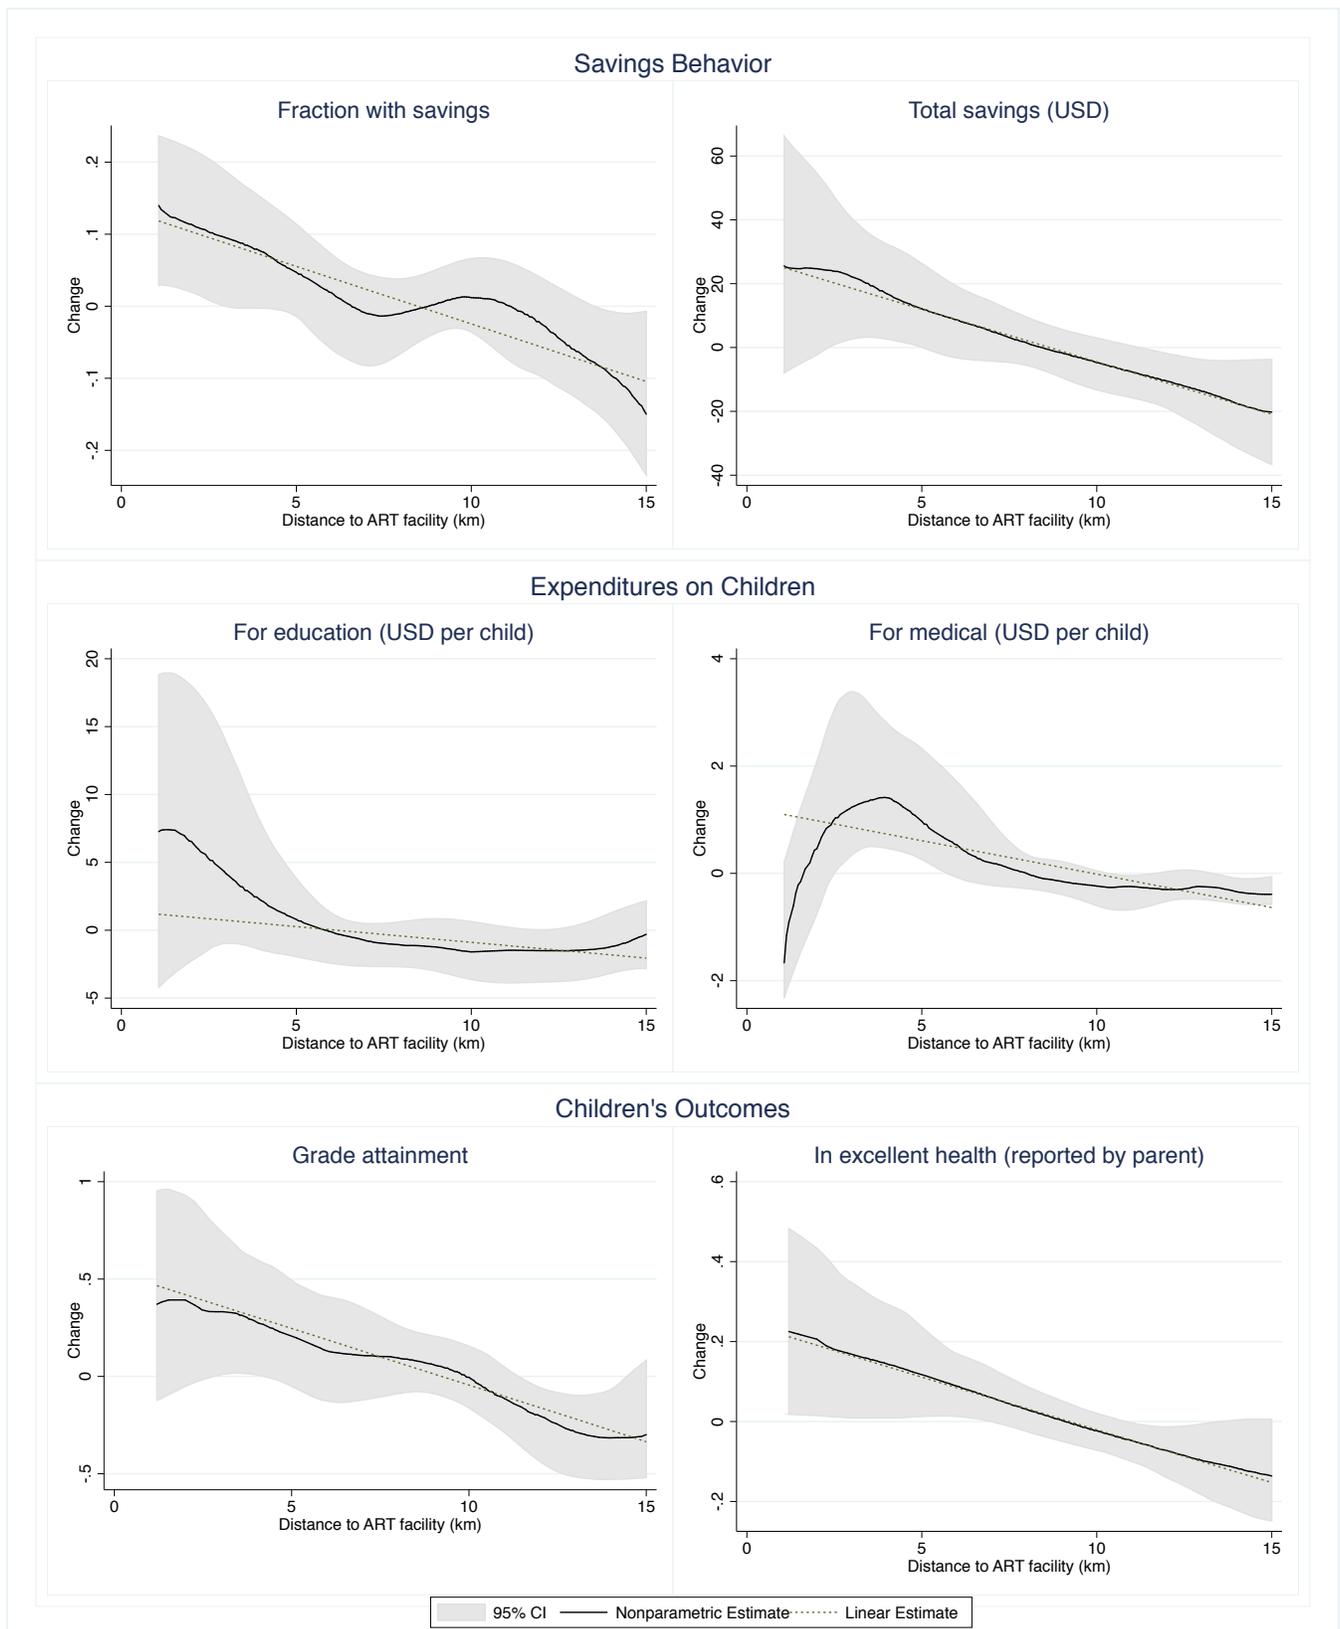

Figure D.5 – Effect of ART by distance

This figure shows nonparametric estimates of changes in the outcome variables by distance to ART. Changes are computed using 2010 as the “post” year, and 2006 and 2004 as the “pre” years (except savings and mortality risk, which do not have 2004 values). This corresponds to the coefficient on $2010 \times ART\ Proximity$ in the parametric results presented in the tables. All graphs are nonparametric local linear regressions with region-year effects partialled out. Confidence bands at the 95% are computed using 1,000 bootstrap replications, clustered by village. In each bootstrap step, and undersmoothed local linear bandwidth is chosen following [Hall \(1992\)](#).

Table D.1 – Pre-characteristics for Attritors

	Sample (1)	Attritors (2)	Coefficient on ART Proximity: (3)

Note: Standard errors (in parentheses) are clustered by village and robust to heteroskedasticity. ART proximity is parameterized as the negative of log distance by road. All regressions include individual fixed effects, region-year dummies, and month of interview controls. The sample is restricted to respondents with school-age children and regressions are weighted by inverse of number of household respondents. All regression use data from 2004. Regressions in columns (1), (5), and (9) are restricted to the balanced panel. Spatial controls include population density and proximity to clinic, market, major road and school (interacted with post). Demographic controls include pre-period wealth, age, household size, gender, education, and marital status. Controls for economic shocks and other aid programs are described in detail in the text. The sample is restricted to individuals who tested negative for HIV in 2008, and excludes individuals who did not consent to the test. The regressions are also done on a perfectly balanced panel, so that respondents have data for all relevant variables in all 4 years of the survey.

Table D.6 – Effect of ART Availability on Schooling and Kids Health

Dependent variable:	Grades completed			In excellent health		
	(1)	(2)	(3)	(4)	(5)	(6)
<i>Panel A: Full sample</i>						
2010 × ART Proximity	0.26*	0.32*	0.34*	0.14**	0.13	0.11
	(0.13)	(0.18)	(0.18)	(0.06)	(0.08)	(0.08)
2008 × ART Proximity	0.06	0.13	0.12	0.12*	0.11	0.09
	(0.09)	(0.14)	(0.14)	(0.07)	(0.08)	(0.08)
Observations	1578	1578	1524	1578	1578	1524
<i>Panel B: Excluding HIV-positive</i>						
2010 × ART Proximity	0.34***	0.39**	0.40**	0.15**	0.13	0.11
	(0.12)	(0.17)	(0.17)	(0.06)	(0.08)	(0.08)
2008 × ART Proximity	0.09	0.14	0.13	0.14**	0.11	0.09
	(0.09)	(0.14)	(0.14)	(0.06)	(0.08)	(0.08)
Observations	1521	1521	1476	1521	1521	1476
Spatial controls	-	Yes	Yes	-	Yes	Yes
Demographic controls	-	-	Yes	-	-	Yes

* $p < .10$, ** $p < .05$, *** $p < .01$

Note: Standard errors (in parentheses) are clustered by village and robust to heteroskedasticity. ART proximity is parameterized as the negative of log distance by road. All regressions include child fixed effects, and region-year dummies. The sample is restricted to children who were reported in all three years of the survey (2006, 2008, and 2010). Regressions are weighted by inverse of number of children per household. Regressions in Panel B exclude children whose parents ever tested positive for HIV.

Table D.7 – Effect of ART Availability on Schooling – DDD

Sample:	All Children			Excluding Children Age < 12 by 2010		
	(1)	(2)	(3)	(4)	(5)	(6)
Girl × 2010 × ART Proximity	0.27	0.19	0.22	0.38*	0.30	0.33
	(0.21)	(0.21)	(0.20)	(0.22)	(0.22)	(0.21)
Girl × 2008 × ART Proximity	-0.03	-0.11	-0.10	0.00	-0.08	-0.08
	(0.15)	(0.16)	(0.15)	(0.16)	(0.17)	(0.16)
2010 × ART Proximity	0.24*	0.30	0.31*	0.25*	0.29	0.29
	(0.13)	(0.18)	(0.18)	(0.14)	(0.19)	(0.19)
2008 × ART Proximity	0.09	0.15	0.16	0.10	0.13	0.14
	(0.11)	(0.16)	(0.16)	(0.11)	(0.16)	(0.16)
Spatial controls	-	Yes	Yes	-	Yes	Yes
Demographic controls	-	-	Yes	-	-	Yes
Observations	1521	1521	1476	1368	1368	1323
Within R2	0.69	0.69	0.70	0.69	0.70	0.70

* $p < .10$, ** $p < .05$, *** $p < .01$

Note: Standard errors (in parentheses) are clustered by village and robust to heteroskedasticity. ART proximity is parameterized as the negative of log distance by road. All regressions include child fixed effects, and region-year dummies. The sample is restricted to children who were reported in all three years of the survey (2006, 2008, and 2010). Regressions are weighted by inverse of number of children per household. Regressions exclude children whose parents ever tested positive for HIV. Columns (1)-(3) use the full sample of children aged 5-19, and Columns (4)-(6) only include children who were older than 12 years old by 2010.
